Abstract
Introduction: Desmoplastic fibroma is an extremely rare, locally aggressive, benign bone tumour with incidence of 0.1% of primary bone tumors. It is composed of spindle cells with minimal cytological atypia and abundant collagen. Diagnosis is made on radiology and histopathology.

Case Summary: A 17yr female patient presented with pain and swelling in left forearm since 9yrs, slowly progressive in nature. Radiograph showed an osteolytic lesion of the proximal ulna. En-bloc excision was done. Grossly the tumor was 13x6x2.5cm, hard in consistency with grey-white mass on cut section. Microscopically it was composed of spindle shaped cells with elongated bland appearing nuclei arranged in whorled pattern and fascicles with abundant collagen present between spindle cells. No pleomorphism or mitoses were noted.

Conclusion: Desmoplastic fibroma is a very rare locally aggressive benign neoplasm of bone. The diagnosis and management are often difficult and requires a combined speciality approach.

Keywords: Desmoplastic fibroma, Ulna, Bone tumor, Spindle cell, Collagen.

Introduction
Desmoplastic fibroma is an extremely rare, benign, well-differentiated, locally aggressive bone tumour with an incidence of 0.1% of all primary bone tumors and characterised by spindle cells with minimal cytological atypia and abundant collagen production. Jaffe in 1958, first described desmoplastic fibroma as a primarily osseous-arised aggressive fibromatosis of femur, tibia and scapula. Desmoplastic fibroma was considered to be the osseous counterpart of extra-abdominal desmoid tumour because of the infiltrative pattern of growth. It commonly involves the jaw, femur and tibia, although any bone may be involved. Involvement of the bones of forearm is an extremely rare occurrence.

Patients present with a variety of symptoms including pain, swelling, deformity or loss of function.

Plain radiographs reveal a trabeculated, lucent, expansile lesion often with lobulated margin.

We report a case of desmoplastic fibroma of ulna involving proximal two thirds.

Case Report
A 17 years old female patient presented with complaints of progressively increasing swelling and pain in left forearm since 9 years.

On clinical examination there was tenderness and swelling in the upper part of the left forearm. (Fig. 1)

On plain radiograph, an expansile, osteolytic lesion with thinned out cortex involving proximal two-thirds of ulna was noted, lesion was located in the diaphysis, with extension to metaphysis & epiphysis. No matrix was noted. (Fig. 2)

Excision of the tumor was performed and fibular graft was used to reconstruct elbow. Tenodesis of fibular head was done with triceps muscle.

Grossly, the tumor measured 13cm x6 cm x 2.5cm. Cut surface was homogeneous, firm, grayish white in appearance, involving the entire bone with cortical thinning. (Fig. 3 a & b)

On microscopic examination, the tumor composed of interlacing fascicles and whorls of spindle cells with an elongated and bland nuclei. Abundant collagen was present between the spindle cells. Areas of normal osteoid was also seen. No pleomorphism, no cytologic atypia and no mitoses. (Fig. 4 & 5)

A diagnosis of desmoplastic fibroma was made based on the radiological and histopathological findings.
Fig. 2: X-ray showing lytic lesion in the proximal ulna involving the epiphysis

Fig. 3: (A) Surgical specimen of the excised tumor; (B): Cut section showing gray white tumor involving the entire bone

Figure 4: (A) Low magnification view showing fascicles of spindle shaped cells with dense collagen; (B): High magnification view showing bland spidle cells
Assessment of lesional cells in cellular atypia and lytic lesions giving radiological imaging alone as many tumours have disease and margins. The degree of cellularity is variable but cellular atypia and pleomorphism are minimal or absent. Mitoses are rare. The tumour can show variable cellularity ranging from mild, moderate or high with or without bone involvement. Immunohistochemistry does not aid in the diagnosis as the lesions of desmoplastic fibroma are usually positive for vimentin, which is a nonspecific and non-diagnostic finding. No specific, reliable IHC marker(s) for labeling lesional cells in desmoplastic fibroma have been recognised; therefore, it remains a diagnosis of exclusion.

Differential diagnosis of desmoplastic fibroma include benign and malignant spindle cell tumors. Low grade fibrosarcoma is extremely difficult to distinguish, however fibrosarcomas will have cellular atypia, occasional mitotic figures, and a “herringbone” arrangement of cells. Fibrous dysplasia with woven bone and non ossifying fibroma can mimic desmoplastic fibroma, but distinction can be made based on the characteristic radiographic findings. Microscopically fibrous dysplasia storiform pattern of spindle cells admixed with multinucleated giant cells and foam cells and in case of fibrous dysplasia, searching for woven bone can help, also the nuclei in fibrous dysplasia are shorter and more compact-looking than the elongated, slender nuclei seen in desmoplastic fibroma.

Treatment for desmoplastic fibroma tumor is marginal or wide surgical excision. Aggressive curettage is also recommended in view of its high recurrence rate. Other treatment strategies include radiotherapy and pharmacological treatments if needed. In cases where resection cannot be done adjuvant radiotherapy helps in controlling recurrence. Free fibular grafts are used for reconstruction of the upper limb.
Conclusion

Desmoplastic fibroma is a very rare, benign, well differentiated spindle cell tumor. It is locally aggressive tumor and because of high recurrence rate it needs to be distinguished from other benign spindle cell lesion by clinical, radiological and histopathological correlation.
