Abstract
Palatal impaction of maxillary canine is the most common amongst the canine impactions with several treatment options proposed for it. Therapeutic extractions are most of the times controversial. This case report describes the diagnosis and treatment of palatally impacted maxillary canine by surgical exposure and orthodontic positioning of it.

Keyword: Closed flap technique; Impaction; Lateral incisor extraction; Maxillary canine, Surgical exposure.

Introduction
Impaction refers to failure of a tooth to emerge into the dental arch. The etiology of impaction is multifactorial. Some of the causes are: genetic predisposition, developmental anomalies, syndromes, inadequate arch space. Maxillary canines have the longest period of development, the deepest area of development, and the most difficult path of all the teeth. Canine impaction is more prevalent in the maxilla than in the mandible.

Palatal displacement of the maxillary canines is defined as the developmental dislocation to a palatal site often resulting in tooth impaction requiring surgical and orthodontic treatment.

Few authors studied the factors affecting the management of impacted maxillary permanent canines and they stated that, the decision to expose or remove an impacted maxillary permanent canine seemed to be guided by the labiopalatal crown position and angulation to the midline.

Some authors believed that asymptomatic impacted teeth could be left in place, but in these patients a series of successive radiographs should be taken periodically.

The purpose of this paper was to describe the diagnosis and treatment of palatally impacted maxillary canine by surgical exposure and orthodontic positioning of it.

Diagnosis and etiology: A 15 year 6 months old girl reported with a chief complaint of missing upper front tooth and wanted to get the treatment done for the same. She was physically healthy and had no history of medical or dental trauma. No signs or symptoms of Temporomandibular joint dysfunction were noted at the initial examination.

The extraoral clinical examination (Fig. 1) showed a slight concave profile with average nasolabial angle. There were no gross asymmetries. The intraoral examination (Fig. 1 and 2) showed an Angle’s Class II div 1 subdivision malocclusion and Class I incisor relationship with retained upper right deciduous canine. The maxillary right permanent canine was impacted. The maxillary arch showed space shortage of 8mm and the mandibular arch showed moderate crowding of 8mm. There was increased overbite of 4mm and overjet of 2mm.

Cephalometrically (Fig. 3), the patient had a Class III skeletal relationship (ANB angle: -3°) with both maxillary and mandibular retrognathism (SNA: 71°).
SNB: 74°). A vertical growth pattern was seen
(SNA:GoGn: 38°). Maxillary incisors were proclined
with the upper incisor at 10 mm and 29° to NA. The
lower incisors were retroclined with an IMPA of 86°
and the lower incisor at 23° and 3 mm to NB, resulting
in a reduced interincisal angle (Table 1). The panoramic
radiograph showed all permanent teeth with a retained
deciduous upper right deciduous canine, including the
maxillary and mandibular unerupted third molars. The
maxillary right canine was impacted (Fig. 3). The
palatal position of the impacted maxillary canine was
confirmed with the help of maxillary occlusal
radiograph.

Bayesian network analysis(10)(Fig. 4 and Table 2)
on the Orthopantomogram tracing was done to evaluate
the possible relationships among the variables
considered for diagnosis and treatment of impacted left
mandibular canine. The favorability of the impacted
canine to erupt into the arch was analysed and it was
found to be good.

Treatment objectives: The initial treatment objective
was to disimpact the maxillary right canine and bring it
into alignment. The orthodontic procedure would align
the maxillary and mandibular dental arches. Our
treatment objective also included maintaining Class III
skeletal relationship, bringing the end on molar
relationship on right side into full cusp Class II molar
relationship and maintaining the Class I molar
relationship on the left side with, achieving Class I
canine relationship with a pleasing profile and to
improve the smile arc.

Treatment alternatives: Three alternatives were
presented to the patient.
1. Extraction of maxillary and mandibular first
premolars. The two main advantages of this
treatment option were the efficiency to bring the
impacted maxillary right permanent canine into
alignment in the arch with space created by
extraction of premolars. Nevertheless, mandibular
first premolars extraction treatment would not
resolve the arch length discrepancy but would end
up in excess space. It also would not achieve ideal
incisal relationship and might even worsen the
profile, resulting in excess of overjet.
2. Extraction of the mandibular left lateral incisor.
This would address the arch length discrepancy in
lower arch. The non-extraction treatment plan of
maxillary arch, would help in good arch alignment

Indian Journal of Orthodontics and Dentofacial Research, April-June 2017; 3(2): 119-123
by gaining space for it through arch widening. However, the facial and smile esthetics would not be optimized.

3. Extraction of maxillary right first premolar and mandibular left lateral incisor. This would create sufficient space to bring the impacted maxillary right canine into alignment and occlusion. The arch-length deficiency in mandibular arch would be resolved. This would enhance both the profile and the smile esthetics by achieving ideal incisal and canine relationship.

The third treatment option was adopted because it would optimize facial and smile esthetics. Co-operation and stability issues were discussed with the patient.

**Treatment progress:** Both the esthetic concerns and the patient’s desires called for a challenging solution for an unusual impacted maxillary canine treatment to align into its ideal position in the arch. The preoperative orthodontic preparation was performed with conventional 0.022-in MBT appliances. The initial alignment and leveling was achieved with 0.016” NiTi archwires. The impacted maxillary right canine was surgically exposed and bonded during the 0.018’ AJ Wilcock archwire stage. The impacted maxillary canine was exposed with closed flap surgical approach palatally. The maxillary right retained deciduous canine and first premolar of the same side were extracted immediately after bonding the Begg bracket on the palatal surface of the exposed tooth (Fig. 5). The ligature wire was tied from the bonded attachment on the canine. Surgical exposure was carried out under local anesthesia. The alignment and leveling was completed with .019 X 0.025-in NiTi and 0.019 X 0.025-in stainless steel rectangular archwires. Elastic traction was given from the ligature wire attached to the Begg bracket on the exposed crown of the impacted maxillary right canine to the 0.019 X 0.025 stainless steel maxillary arch wire. In order to bring the maxillary right canine in the arch, a overlay (“Piggy Back”) wire of 0.014 NiTi, over the 0.019 X 0.025 stainless steel mandibular arch wire was engaged on the Begg bracket of the maxillary right canine. The overlay wire extended from second premolar on right side to the second premolar on the left. As the maxillary right canine started erupting, MBT 0.022 maxillary right canine bracket was bonded on the labial surface of the tooth and couple force was given in order to de-rotate the tooth (Fig. 6). After the maxillary right canine was brought into the arch, the Begg bracket on its palatal surface was debonded. Settling was done with 0.014” Stainless steel archwire. This entire orthodontic procedure took 18 months.

**Treatment results:** The facial esthetic was improved with better lip support, maintaining the average nasolabial angle (Fig. 7). The smile was enhanced and the consonant smile arc was achieved. Intraorally, ideal overjet and overbite was achieved with Class I canine relationship. The end-on molar relationship on the right side was brought into full cusp Class II molar relationship while the Class I molar relationship on the left side was maintained.

The post treatment panoramic radiograph (Fig. 8) showed good overall root parallelism and lack of root resorption. Post treatment lateral Cephalogram(Fig. 8) showed satisfactory improvement in ANB angle by 1°. The position of lower incisors were improved, with lower incisor at 25° and 4mm to NB. The arch length discrepancies in both upper and lower arches were
resolved. A favorable profile change in facial profile contoural angle was seen.

**Discussion**

Canines are important in establishing and maintaining the dentition’s form, function and esthetics. The maxillary canine is one of the most frequently impacted teeth with an incidence of 2% with palatal impaction being most commonly seen in 85% of ectopically positioned maxillary canines. Diagnosis and localization is the most important step in the management of impacted teeth. Surgical exposure of the impacted maxillary canine and the use of fixed orthodontic appliances is the most frequently used treatment alternative as long as the tooth position is favorable. Various methods have been used for moving the canine into proper alignment. The procedures used for surgical exposure and traction are important in any impaction case.

Guiding the tooth into occlusion requires a team approach. Surgical exposure of the impacted tooth involves placing a full thickness mucoperiosteal incision and exposing the tooth under local anaesthesia. This may be carried out via an open or an alternative approach known as closed method. The main advantage of closed eruption method was it provided better periodontal health compared to canines managed with open method, with less recovery period with this closed technique.

Class II Subdivisions are difficult to treat, owing to an asymmetric occlusal relationship. Owing to the complexities, regarding the cause, the treatment planning may vary in clinician’s hands. In our case, we took the decision to extract the maxillary right first premolar so as to gain sufficient space for alignment of impacted maxillary canine as well to achieve full cusp class II molar relationship by protracting maxillary right first molar.

Therapeutic extraction has been one of the major controversies in orthodontics. The teeth most commonly extracted for orthodontic treatment (therapeutic extraction) are either first premolar or second premolar. In case of borderline space discrepancy, extraction of premolar might create more than required amount of space. In such cases of borderline space discrepancy in mandibular arch, a better alternative is to follow an atypical therapeutic extraction viz extracting one or two mandibular incisors. The concept of removing the lower incisor for the purpose of relieving the crowding was introduced by Hahn. The critical decision of which incisor to extract depends on several considerations, mainly periodontal conditions, mesio-distal width of each tooth etc. It is especially suitable for patients with mild skeletal Class III malocclusion.

All the advantages and disadvantages of surgical and orthodontic repositioning as well as the risks (including that of being unable to achieve the desired goals) and the need for good cooperation were discussed, and these were understood and accepted by the patient.

**Conclusion**

A pleasing external soft tissue profile was achieved. The combined effect of surgical exposure of impacted maxillary canine and orthodontically correcting its position was instrumental in reestablishing the major components of a balanced smile for this patient, whose main concern was her unpleasant smile.
