Abstract

Plantaris muscle though a vestigial muscle and absent in 10% of cases still has a diagnostic and clinical importance e.g., of its being an isolated cause of tennis leg. This study was done on 50 lower limbs of 25 adult cadavers for morphology and prevalence of plantaris muscle in our region. We have observed absence of plantaris muscle in about 26% of limbs and both belly and tendon of the plantaris muscle had a wide variation in its length and width. In two of the limbs double head of origin of muscle was seen.

Keywords: Double Head, Plantaris, Vestigial.

Received: 18th August, 2017

Accepted: 02nd December, 2017

Introduction

Plantaris muscle takes origin from lower part of the lateral supracondylar line of femur and oblique popliteal ligament of the knee joint. Its 7-10cm long belly ends in a slender tendon which runs obliquely between gastrocnemius and soleus and fuses with calcaneal tendon or inserts with it. It gets its nerve supply from nerve to lateral head of gastrocnemius, a branch of tibial nerve. Sometimes it may have double origin or its tendon may merge with flexor retinaculum or with fascia of the leg.¹ As reported in literature, it is absent in 10% of cases and has been found to be an isolated cause of tennis leg. Though believed to be a vestigial muscle in human beings, it still has a wide clinical and diagnostic importance. Hence correct knowledge of its presence and appearance is important to avoid error in day to day clinical practice by radiologists, orthopaedists and physiotherapists.

Materials and Methods

The study was done at R.N.T. Medical College, Udaipur on 50 lower limbs of 25 embalmed cadavers (19 males and 6 females) for a period of two years (2015-2017). All the cadavers were of the age group 50-60 years. None of them had any congenital anomalies. Limbs with any scar mark due to injury or surgery were excluded from the study. Dissection of posterior compartment of thigh and leg was done according to the steps described in Cunningham's Manual of Practical Anatomy.² Measuring tape and vernier calipers were used to

measure the length and breadth respectively of the muscle and its tendon respectively.

Observations

Detailed morphological study of plantaris muscle was done and following parameters were recorded-
Origin and insertion of the muscle. Length of muscle belly and tendon were measured with the help of measuring tape and were recorded on a paper. Thickness of muscle belly and its tendon were measured with the help of vernier callipers. Any variation in origin or insertion was also recorded and photographed.

Results

Total lower limbs studied-50 (25 Cadavers-19 Males and 6 Females)
The muscle in 48 lower limbs originated normally from the lower part of lateral supracondylar line of femur. (Fig.1) In two cases variations in origin of muscle were seen:

Fig. 1: Plantaris Muscle

In cadaver no. 6 (Fig. 3) Double head of origin of plantaris muscle was noticed in right lower limb. One head was from the lower part of supracondylar line of femur and additional head was from extra articular outer brim of the lateral tibial condyle posteriorly. Tendon of both the

heads were fused and inserted normally. Nerve supply of both the heads was from nerve to lateral head of gastrocnemius, branch from tibial nerve.

Fig. 2: Double Belly of Plantaris Muscle

Fig. 3: Double Belly of Plantaris Muscle

In cadaver no. 8 (Fig. 2) Double head of origin of plantaris muscle was observed in left lower limb. One head originated normally from the lower lateral supracondylar line above the origin of lateral head of gastrocnemius, while additional head originated along with the lateral head of gastrocnemius. Nerve supply of both the heads was from nerve to lateral head of gastrocnemius, branch from tibial nerve. Tendons of both the heads fused and inserted normally along with tendocalcaneus.

No variation in insertion was observed. Tendon of muscle ran on medial side of tendocalcaneus and was either attached to the medial side of calcaneum or was fused with tendocalcaneus.

Variations were noticed in length and width of muscle belly.

Discussion

Gastrocnemius, soleus and plantaris muscles are collectively referred as triceps surae muscle. Plantaris muscle is vestigial in humans, being absent in about 10% of individuals. Cruvehiller³ was first to describe plantaris as vestigial assuming that as our forefathers have assumed an erect posture and plantaris muscle has lost its original attachment to plantar aponeurosis and

has gained a secondary attachment to calcaneum due to special development of calcaneal protuberance. In terms of function, the plantaris muscle acts with the gastrocnemius and is insignificant as either a flexor of the knee, or a plantar flexor of the ankle. It has been thought to be an organ of proprioceptive function for the larger, powerful plantar flexors, as it contains a high density of muscle spindles.⁴

Normally the length of belly of muscle ranges from 7-13cm varying highly in size and form. In our study length of muscle belly was found to be in the range of 2.5-14 cm. Average length of tendon was 31.75cm which was more on left side (32.4 cm). Aragao et al⁵ have reported average length to be 33.26 cm. Najma Mobin⁶ (2016) has observed mean length to be 32.32 cm. Out of 50 lower limbs studied 13 (26%) showed absence of plantaris muscle which varies with study by Aragao et al⁵ wherein plantaris muscle was present in all the 20 cases. While in a study on 60 lower limbs by Najma Mobin⁶ (2016) there was absence of plantaris in only two of lower limbs and that also bilaterally in same cadaver. Simpson et al⁷ has reported rate of absence to be between 7-20%. In addition in our study we have found double head of origin of plantaris muscle in 2 cadavers. (Fig. 2, 3) Double head of plantaris have been reported by Sawant et al,⁸ Rana et al⁹ and Srimani et al.¹⁰ Srimani et al¹⁰ have observed a rare course of common tendon of both the head deep to both the heads of gastrocnemius and soleus.

Plantaris muscle has a long and thin tendon which may be mistaken for a nerve. Moreover tendon may fuse superficially with fascia of leg, making it vulnerable for injury. Surgeons operating in posterior compartment of leg must be aware of superficial position of tendon and its resemblance to nerve.

Variations in plantaris muscle in terms of its distinct interdigitations with lateral head of gastrocnemius or having a strong fibrous extension to patella may be responsible for patellofemoral pain syndrome.¹¹

Tennis leg, a relatively common clinical condition, can be due to various aetiologies like tear of medial head of gastrocnemius, soleus tear, plantaris tear or a combination. Powell¹² in 1883 was the first to describe isolated rupture of plantaris to be a cause of tennis leg. Ultrasonographic imaging, MR imaging and surgical exploration have shown that injury to plantaris muscle may occur alone or in association with tear to anterior cruciate ligament, gastrocnemius or soleus muscle. Hamilton¹³ (1997) has surgically confirmed isolated rupture of plantaris muscle to be a cause

of pain and swelling in calf region. On MR imaging a mass later shown to be benign resolving haematoma by excisional biopsy was found between medial head of gastrocnemius and soleus muscle in this case. A complete tear of plantaris muscle was present without any damage to gastrocnemius and soleus muscle. Delgado et al¹⁴ has also reported isolated rupture of plantaris muscle to be a cause of tennis leg in 1.4% of cases out of 141 cases studied by him.

Tendon of plantaris due to its excellent tensile strength has been successfully used as a graft for reconstruction of flexor tendon in hand and anterior talofibular and calcaneofibular ligament of ankle.¹⁵ It has also been tried for atrioventricular valve repair.¹⁶

A complete plantaris rupture which usually occurs at myotendinous junction will result in proximal retraction of the muscle and on MR imaging this appear as a mass between popliteus tendon anteriorly and lateral head of gastrocnemius posteriorly. Bianchi et al¹⁷ has reported that isolated midsubstance complete tear of plantaris tendon must be differentiated from thrombophlebitis and partial Achilles tendon tears. According to them comparing MRI imaging to ultrasound imaging, later was faster and cheaper.

Though plantaris—regarded as a vestigial muscle, its importance as a cause of tennis leg must be kept in mind in a patient of painful calf syndrome. Moreover, it has been used as a graft in reconstruction surgeries, so variations like double head or absence must be known to the surgeons working in this region.

Conclusion

Presence or absence and variations of plantaris muscle is not only of academic interest to anatomists but also for clinicians especially orthopaedists, plastic surgeons and radiologists in making clinical diagnosis and imaging of painful calf syndrome.
